Postlarval and juvenile fish (*Pisces*,
Perciformes and *Myctophiformes*) in
the Antarctic Peninsula region
during BIOMASS-SIBEX,
1983/1984*)

ABSTRACT: During the SIBEX¹⁾ programme in December 1983/January 1984, 27 hauls were made from the "Profesor Siedlecki" with a 368 — mesh midwater sampling trawl. A total of 13 fish species at postlarval or juvenile stages was found in the catches. The greatest abundance and species diversity of juvenile ichthyofauna was observed within shelf waters of the Peninsula. Postlarval and juvenile *Pleuragramma antarcticum* was the most common and most abundant species there.

Key words: Antarctic, BIOMASS-SIBEX juvenile fish

1. Introduction

The knowledge about juvenile Antarctic ichthyofauna in the pelagic phase of its life is still insufficient to understand the mechanisms governing its distribution and migrations, determine the factors influencing its individual development and survival rate, as well as establish the interrelations between juvenile fish and the pelagic ecosystem of the Antarctic. More extensive and thorough observations and investigations of the problem were commenced at the end of the 1970's (Rembiszewski, Krzeptowski and Linkowski 1978, Kompowski 1980 a,b, Ślósarczyk 1983a). The FIBEX programme was the first attempt at a presentation of information concerning the distribution and abundance of postlarval and juvenile fish against the background of hydrological conditions prevailing in the areas of study (Kellermann and Kock 1984, Kellermann and Ślósarczyk

¹⁾ Second International BIOMASS Experiment

*) Investigations were supported by the Polish Academy of Sciences (Project MR-I-29A).

1984). In the first phase of SIBEX, a programme of ichthyological investigations of the FIBEX expedition was repeated on the r/v "Profesor Siedlecki"; at the same time, a new small midwater trawl, designed especially for these investigations, was used to catch juvenile fish (BIOMASS Working Party on Fish Ecology 1982).

2. Material and method

In December 1983/January 1984, 27 hauls were made from the r/v "Profesor Siedlecki" (Fig. 1). For sampling a small, 368-mesh midwater

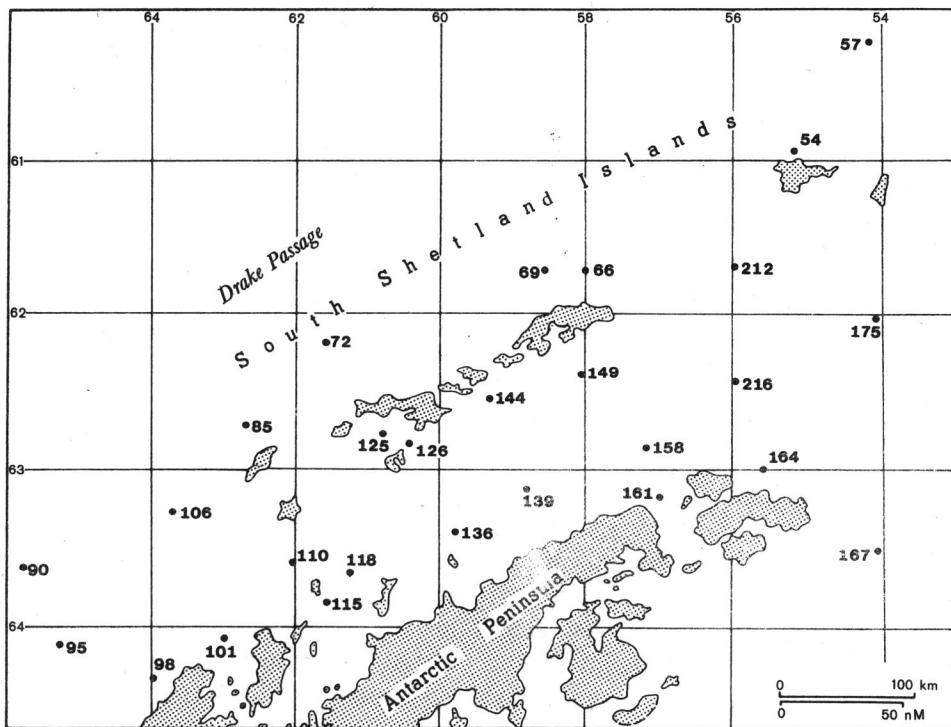

Fig. 1. Sampling trawl stations of r/v, "Profesor Siedlecki" during SIBEX (21 December — 8 January 1983/1984)

trawl was used. The fine-meshed inset with a bar length of 15 and 12 mm was attached to the belly and 10 mm inset to the cod-end of the trawl. Approximate vertical and horizontal opening of the trawl was 9 and 14 m, respectively, at a mean speed of trawling of 3 knots.

Fourteen hauls were made at preselected stations; haul duration was usually 30 minutes and 3–5 depth levels were sampled: 10–15 m, 25–30 m,

50—55, 70—75 m, 95—110 m. Because of the expected short duration of investigations (December 21-January 8) these stations were mostly established on the shelf and continental slope of the investigated area since it was assumed that outside this zone, juvenile fish occur rarely (Śłosarczyk and Rembiszewski 1982, Kellermann and Śłosarczyk 1984). The remaining hauls were made in order to determine the presence of fish in the vicinity of krill or salp patches recorded on the echosounder.

The whole catch or a random sample taken from it (when the numbers of krill were large) was sorted out, than weighed or counted. When determining c.p.u.e. for fish, two measures were used (1) number of specimens caught in 1 hour fished, and additionally (2) number of specimens in

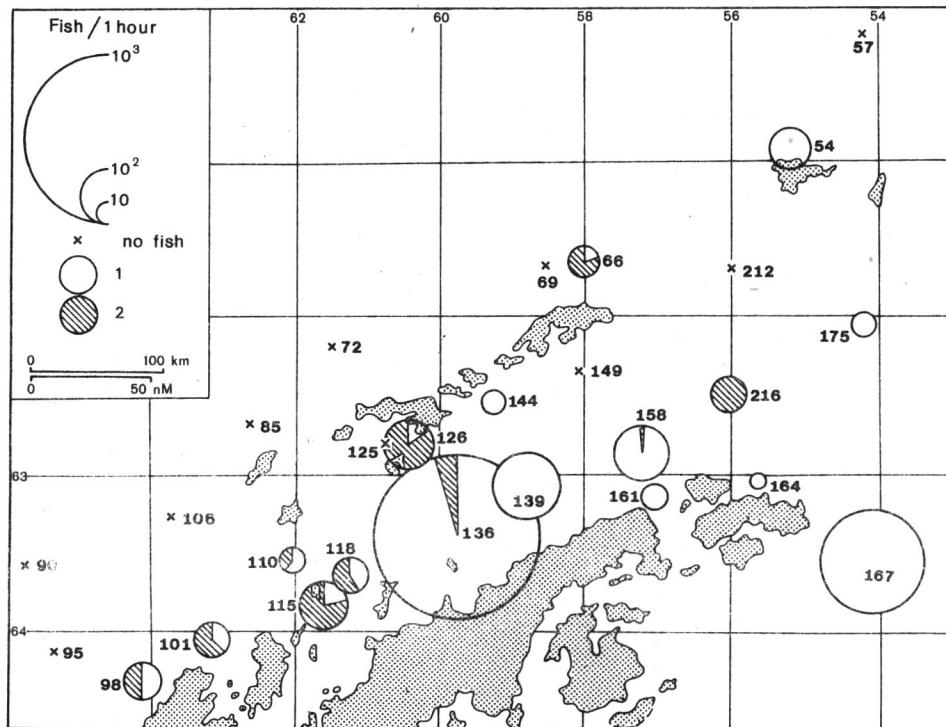

Fig. 2. Distribution and abundance (No. per 1 hour of trawling) of juvenile *Nototheniidae* (1) and *Chaenichthyidae* (2) in the Antarctic Peninsula region during SIBEX (21 December — 8 January 1983/1984)

100 kg of krill, when fish were caught together with krill. For further investigations, postlarval and juvenile fish were preserved in 4% formaldehyde buffered with borax, in alcohol, or Dorogostaisky's solution (Śłosarczyk and Rembiszewski 1982).

3. Results

Species composition of total trawl catches is presented in Table I. The data contained in the table should not be treated in the same way as the results of quantitative macrozooplankton catches by means of Bongo or RMT nets because of relatively large mesh size in the belly and cod — end of the trawl. However, they could supply some information about pelagic fauna, among which postlarval and juvenile stages of fish live and develop.

In the 27 hauls made, 21 contained postlarval or juvenile fish. The presence of these fish in the catches was observed almost exclusively in shelf waters, particularly north of Antarctic Peninsula (Table I, Fig. 2). A total of 13 fish species at early developmental stages was found in the catches (Table II). The most abundant and most often encountered was *Pleuragramma antarcticum* (*Nototheniidae* — Fig. 2, Table II) at a postlarval and juvenile stage. Postlarval *Cryodraco antarticus*, *Chaenodraco wilsoni* and *Chionodraco rastropinosus* were also often encountered.

Fishes were associated with krill aggregations occurring in relatively shallow waters, north of Palmer Archipelago and in single hauls near the Livingstone I., King George I. and Elephant I. (Table III). Fishes were not found or were very rare within krill concentrations observed far from coasts of the islands.

4. Discussion

When compared with the results of FIBEX (Kock 1982, Śłósarczyk and Rembiszewski 1982, Kellermann and Kock 1984, Kellerman and Śłósarczyk 1984), fewer fish species were observed in the pelagic zone of the study area; prevailing species also differed in 1981 and 1983/1984. Two factors were responsible for this, according to the authors: a different season of the year and a different hydrological situation. Polish investigations within the SIBEX programme were carried out two months earlier than FIBEX and that is why certain species — if the growth and development of fish were similar — were still too small to get stuck in the relatively large meshes of the trawl inset while other species did not yet go beyond the coastal zone of the adjoining islands, where their spawning grounds were located. Such an opinion is confirmed by the results of catches of fish larvae by means of plankton nets, made in the vicinity of trawling stations as well as observations from 4-day long krill catches in coastal waters of Elephant Island directly after SIBEX programme (Śłósarczyk, in print). The different hydrological situation helps to explain the

abundant appearance of *Pleuragramma* in the catches. Eight out of ten hauls in which this species was observed were made over the shelf of the Antarctic Peninsula. During the period of investigations, the whole southern part of the Bransfield Strait was under the influence of waters from the Weddell Sea, flowing eastwards (Grelowski — pers. comm.). It may be expected that before our investigations began, a strong inflow of Weddell Sea waters to the Strait had taken place and in this way *Pleuragramma* was carried there from the areas of its greatest concentrations in the south-eastern part of the Weddell Sea (Keller 1983).

The abundance of postlarval and juvenile fish in krill catches was similar to that observed during FIBEX (Ślósarczyk and Rembiszewski 1982, Kellermann and Kock 1984). A more detailed comparison of the results of FIBEX and SIBEX is not possible because the distribution of krill was quite different in the two seasons and krill concentrations in the Bransfield Strait were not present. However, a preliminary conclusion may be drawn from the results of the two programmes that juvenile fish off the Antarctic Peninsula do not occur in December-March in such great numbers within krill concentrations as off South Georgia (Komppowski 1980a, Ślósarczyk, 1983b, off the Balleny Is. (Ślósarczyk 1983) or in the Prydz Bay (Ślósarczyk, unpublished). Thus, in that period, off the Antarctic Peninsula, the krill fishery does not constitute such a large threat to the survival rate of juvenile fish as is the case in the above-mentioned areas which, incidentally, belong to the traditional, heavily exploited krill fishing grounds. This opinion does not refer to certain species, observed during FIBEX exclusively in the shelf zone of the Antarctic Peninsula (Ślósarczyk and Rembiszewski 1982, Kellermann and Ślósarczyk 1984), for which the danger still exists. Among these are species from families *Bathydraconidae* and *Harpagiferidae*, as well as some *Channichthyidae*, considered rare species or species with low fecundity (Permitin 1973) and therefore thought worthy of protection.

The authors would like to express thanks to the participants of the cruise, Dr Z. Witek and Dr W. Kittel for their help in determining the taxonomic affinity of macrozooplankton from trawl catches and Mr S. Licherowicz from the Sea Fisheries Institute for preparing figures and tables.

5. Резюме

Согласно программе экспедиции СИБЭКС, в период с 21 декабря 1983 года по 8 января 1984 года проведено попытку оценки присутствия и численности в пелагиали молоди антарктических рыб с помощью специально сконструированного для этих исследований малогабаритного траула.

В 27 тралениях, проведенных в акватории севернее Южных Шотландских островов и Пальмерских островов, а также в Брансфильдском проливе (рис. 1., таблица I)

обнаружено присутствие 13 видов рыб в постларвальной или ювенальной стадиях развития (таблица II). Наибольшую разновидность и численность ювенальной ихтиофауны наблюдали в шельфовых водах Антарктического полуострова (рис. 2). Чаще всего и в наибольшей численности в этом районе встречались постларвальная и ювенальная стадии *Pleuragramma antarcticum* (таблицы II и III). Кроме этого вида часто встречалась молодь видов *Cryodraco antarcticus*, *Chaenodraco wilsoni* и *Chionodraco rastrospinosus*.

Сравнивая результаты исследований с результатами программы ФИБЭКС, в пелагиали исследуемого района наблюдали более убогий видовой состав, а также различие их численного соотношения. Обусловленно это было различием гидрологических условий и времени года, в период которых проводились наблюдения.

По результатам обеих программ можно предполагать, что в районе Антарктического полуострова и Южных Шотландских островов в период с декабря по март, в соседстве промысловых скоплений криля молодь рыб не встречается в такой численности, как в других районах Антарктики (Южная Георгия, острова Баллены, залив Придз). Не смотря на это в исследуемом районе промысел криля становится угрозу уменьшения выживаемости молоди, обитающих в этом районе видов рыб с низкой степенью воспроизводительности, а также редко встречающихся видов рыб.

6. Streszczenie

W programie SIBEX, w okresie od 21 grudnia 1983 do 8 stycznia 1984, dokonano próby oceny rozmieszczenia i liczebności w pelagialu młodocianych ryb antarktycznych przy użyciu małego włoka, zaprojektowanego specjalnie do tego programu badań. W 27 zaciągach przeprowadzonych w akwenie na północ od Sztetlandów Południowych i Archipelagu Palmera oraz w Cieśninie Bransfielda (rys. 1, tabela I) stwierdzono występowanie 13 gatunków ryb w postlarwальnym lub młodocianym stadium rozwoju (tabela II). Największą różnorodność i liczebność młodocianej ichtiofauny obserwowano w wodach szelfowych Półwyspu Antarktycznego (rys. 2). Postlarwalna i młodociana *Pleuragramma antarcticum* była najliczniej i najczęściej występującym w tym rejonie gatunkiem (tabele II i III). Obok niej do często notowanych należały *Crydraco antarcticus*, *Chaenodraco wilsoni* i *Chionodraco rastrospinosus*.

W porównaniu z wynikami FIBEX w pelagialu badanego obszaru obserwowano dwukrotnie mniej gatunków ryb, inne również gatunki były dominantami połowów. Wprowadziła na to odmienna sytuacja hydrologiczna i inna para roku, w której przeprowadzono badania. Z wyników obu programów można ostrożnie wnioskować, że w rejonie Półwyspu Antarktycznego i Sztetlandów Południowych, w okresie od grudnia do marca, ryby młodociane nie występują w sąsiedztwie koncentracji kryla tak licznie jak w innych regionach Antarktyki (Georgia Południowa, Wyspy Balleny, Zatoka Prydz). Pomimo tego w rejonie badań istnieje jednak ze strony rybołówstwa krylowego zagrożenie dla przeżywalności młodzieży licznie notowanych tam gatunków ryb o niskiej płodności bądź gatunków uznawanych za rzadko występujące w przyrodzie.
